valuable because they extend into fairly high Reynolds number  $(1.5 \times 10^6)$  and Keulegan-Carpenter number (100), with  $\beta$  (= R/K) values up to 8370. Sarpkaya's work also approximately simulated the orbital motion of waves on a vertical cylinder by sliding the test cylinder, along its axis, into and out of the water tunnel test section, with varying amplitude, synchronized with the water motion period (15).

Wave flow on vertical cylinders has significant differences from the oscillatory flow in a water tunnel. First, the water surface fluctuates on the cylinder between the trough and the crest. There is considerable run-up on the flow side of the cylinder (be it at the crest or the trough of the wave) and depression on the lee side, as shown in Fig. 1. The run-up and depression influences the total forces on the cylinder in a way that has not yet been quantified in the open literature. In addition, the wave flow kinematics decay with depth for all but shallow water waves. Even in carefully controlled laboratory waves with long crests, this attenuation with depth creates unknown differences in the vortex shedding characteristics around vertical cylinders, which probably change with depth. For such waves, one should expect more scatter in laboratory results than with U-tube experiments.

Of course, in the ocean one should expect even more variation of conditions (wide scatter in the results of measurements) because of a greater degree of randomness of the wave heights and periods, various degrees of short-crestedness in the waves, influences from the proximity of other structural members, and varying degrees of surface roughness because of biofouling. In fact, considerably more scatter and uncertainty is displayed for the results reported on in (17) than displayed from the laboratory data reported on here. Short-crestedness may also be important because of the

influence of the wake encounter effect (3). However, controlled laboratory results are useful for gaining basic knowledge on the processes of fluid mechanics. In addition, experiments in large, controlled laboratory waves can provide transition conditions between the highly idealized U-tube experiments and the design conditions of concern in the field.

The experimental data herein provide Reynolds numbers up to  $7 \times 10^5$  in steady flow and  $3.1 \times 10^5$  in periodic waves. The Keulegan-Carpenter number ranges up to maximum values of about 27 in waves, and the maximum values of  $\beta$  are about 40,000. Some 1976 oscillatory cylinder data were also reexamined wherein the maximum Reynolds number was  $7 \times 10^5$ , the maximum Keulegan-Carpenter number was 63, and the maximum  $\beta$  was about 12,000. In the field, under maximum design conditions, one would expect Reynolds numbers in the range of from  $10^6$  to  $2 \times 10^7$ , with Keulegan-Carpenter numbers approximately in the range of from 80 to 240. The associated  $\beta$  values would range from about 12,000 to 80,000. Thus, the work reported herein, which was performed in the Wave Research Laboratory at Oregon State University (OSU), provides information on physical events that are transitional in scale and in fluid flow character between the U-tube experiments of Sarpkaya and the actual events in the ocean, some of which were reported by Heideman, et al., (3).

When reviewing the literature one must be careful to place the various studies into perspective. It is well known that  $C_m$  is a function of both R and K when  $\beta < 6000$ , but that it is approximately equal to 2.0 for all K, when  $\beta > 6000$ . On the other hand,  $C_d$  seems to vary somewhat with K even at  $\beta = 8370$ , the limiting value shown in (14). It is important to combine high K, R, and  $\beta$  values to approach prototype conditions in order to provide best values of  $C_d$  and  $C_m$  for design considerations. Even the field study reported

in (17) yielded maximum K values only on the order of 30. (It is difficult to estimate K from horizontal velocities in that publication, although maximum K values from vertical velocities were at about 15.) The maximum R was about  $5.7 \times 10^5$ , yielding maximum  $\beta$  values of about 19,000. The laboratory experiments in (16) had maximum K values of about 24, but R was not reported although  $\beta$  = 200 was alluded to, but not clearly identified as pertaining to that work. The tests in (1) covered K values up to 40 and again R values were not reported, although they must have been low because the largest cylinder diameter was 3 inches and the largest wave period was 3.5 s.

The force-phase method reported herein has promise of reducing some of the scatter in  $C_d$  and  $C_m$  by means of a suggested alternative method of data reduction and analysis. At least the major source of the scatter is identified to be the shedding of vortices and how they influence the phase between the force measurement and the ambient velocity. Some changes in the analysis were conceived by observing the relative phases in time between the water profile or velocity measurements (which are theoretically in phase), the computed acceleration, and the force measurement. (Details of these experiments will be given later.) An example where the force is nearly in phase with the accleration is shown in Fig. 2. A case where the force is more nearly in phase with the velocity is shown in Fig. 3. These figures support the idea that if K is small, the inertia force dominates (or, the force is more nearly in phase with the acceleration). If K is larger and the cylinder is rough, then the drag force should dominate (or, the force is more nearly in phase with the velocity).

The phases to the maximum force and maximum acceleration in the general vicinity of the wave crest are shown in the figures. A crest-to-crest wave

was chosen for analysis instead of a trough-to-trough wave because the crests are more clearly definable for the larger and longer waves. It turned out that the three phases to the maximum values,  $\phi_{\rm u}$ ,  $\phi_{\rm a}$ , and  $\phi_{\rm f}$ , (velocity, acceleration, force) are closely grouped near the right-hand crest for the waves so defined. It also turned out that the local force was much more influenced by the acceleration term than originally anticipated. In fact, in order to get a record that was more heavily influenced by the velocity term for illustration, it was necessary to use a record for a sand-roughened cylinder, as shown in Fig. 3, in addition to having K much larger than in Fig. 2. Even so, the maximum force is still considerably influenced by the wave accelerations, as shown in the figure. Figure 3 also shows that the "measured" acceleration phase is considerably different than the acceleration phase determined from stream function,  $\phi_{\psi a}$ , or linear wave theories,  $\phi_{La}$ , a condition that will be discussed in more detail later.

It would thus appear to be more direct to examine the relationship of the phase of the force with respect to the ambient velocity and acceleration in determining if conditions are drag or inertia dominant. An early paper to this effect was published (13) which briefly explains the basic ideas involved. It was shown that there may be less scatter in the data when plotting the maximum force coefficient and the phase shift than when plotting  $\mathbb{C}_{\mathbf{d}}$  and  $\mathbb{C}_{\mathbf{m}}$ .

#### Scope

The major purpose of this paper is to make a systematic review of a force-phase method for determining the forces on vertical smooth cylinders from periodic waves. Data from experiments on 8.625-inch and 12.75-inch diameter smooth aluminum cylinders will be analyzed.

#### **ANALYSIS**

# Maximum Force Coefficient, $C_{\mu}$

The maximum force coefficient,  $C_{\mu}$ , is defined as

$$C_{\mu} = \frac{F_{\mu}}{\frac{1}{2} D L_{\rho} u_{\mu}^2} \tag{2}$$

where  $F_{\mu}$  is the maximum force on a cylinder in a wave cycle, L is the length of the cylinder over which the force is considered to act, and  $u_{\mu}$  is the maximum horizontal velocity within the cycle. (In this paper the subscript,  $\mu$ , will be used to indicate maximum values.) The maximum force can be considered near the crest or near the trough of a wave. An idealized record is presented in Fig. 4 as an illustration of several aspects of this analysis.

## Phase Shift of the Force, $\hat{\phi}$

The phase shift can be defined in different ways. Since the maximum force is of prime importance for engineering, the phase shift to the force "crest" in Fig. 4,  $\phi_f$ , will receive most of the consideration here. The same holds for the phase of the acceleration crest,  $\phi_a$ . It is convenient to define two normalized phases for the force crest as

$$\hat{\phi} = \frac{\phi_f}{90} \tag{3}$$

and

$$\widetilde{\phi} = \frac{\phi_{\mathbf{f}}}{\phi_{\mathbf{a}}} \tag{4}$$

wherein, if  $\mathfrak{F} \to 1$ , the force is dominated by the inertia effects (or, it is in phase with the ambient acceleration). Conversely, if  $\mathfrak{F} \to 0$ , the force is

dominated by the drag effects (or, it is <u>in phase</u> with the ambient velocity field). The phases  $\hat{\phi}$  and  $\tilde{\phi}$  are defined separately because it is sometimes useful to obtain  $\phi_f$  easily and directly from a plot of  $\hat{\phi}$ , where  $0 < \hat{\phi} < 1$ . In Eq. (7)  $\phi_a$  can be from the "measured" acceleration, or the theoretical values from the linear or stream function theories. The "measured" value is rarely equal to the stream function value and it is nearly always smaller than the linear value. Usually the value from the stream function theory was used for reasons explained later.

There is at least a passing interest in the conditions at the wave trough, so the relative phase there is defined as

$$\widetilde{\phi}' = \frac{\phi_f'}{\phi_a'} . \tag{5}$$

For a visual determination of the phases, it can be sometimes more convenient to work to the upcrossings and downcrossings, in which case the relative, normalized phase is defined as

$$\hat{\Theta} = \frac{\Theta_f - \Theta_u}{90} \tag{6}$$

or

$$\widetilde{\Theta} = \frac{\Theta_{\mathbf{f}} - \Theta_{\mathbf{u}}}{\Theta_{\mathbf{a}} - \Theta_{\mathbf{u}}} . \tag{7}$$

Some results will be presented that are based on averaging the phase at the upcrossings with the phase at the downcrossings.

Another, more computer-oriented method of determining the phase is by cross-correlation analysis, which itself can be computed by different methods. First, the cross-correlation,  $C_{12}$ , between any two signals (in this case the velocity, u, and the force, F, can be computed from

$$CR_{12}(\tau) = \int_{-\infty}^{\infty} g_1(t) g_2(t + \tau) dt$$
 (8)

where  $g_1$  is the velocity record and  $g_2$  is the force record. We seek the phase (or time) at which  $CR_{12}$  is maximum. In practice, the approximate  $\tau$  for  $F_\mu$  is known á priori. Then,  $\tau$  is simply increased incrementally, calculating CR for each value, until  $CR_\mu$  is reached, by evidence of a reduction in CR. Experiments with other methods, such as finding the  $\tau$  at which  $\partial CR/\partial \tau = 0$ , and spectral methods, have required more computer time and cost. The value of  $\tau$  at which CR is maximum, nondimensionalized by the wave period, and multiplied by  $360^\circ$ , is the force phase, or

$$\phi_{f} = 360 \frac{\tau}{1} . \tag{9}$$

The phase can be also determined by either of two spectral methods. The cross-correlation and certain spectral products are Fourier transform pairs. Specifically, the spectral product,  $E_{12}$  (f), is defined as

$$E_{12}(f) = S_2(f) S_1^*(f)$$
 (10)

where

$$S_n(f) = \int_{-\infty}^{\infty} g_n(t) e^{-j2\pi ft} dt, \qquad n = 1, 2$$
 (11)

and \* indicates the complex conjugate. Then  $CR_{12}$  ( $\tau$ ) and  $E_{12}$  (f) are Fourier transform pairs. However, obtaining the Fourier transform of Eq. (10) (which yields CR for all values of  $\tau$ ) usually requires more computer time than a few direct computations of Eq. (8). An alternative procedure is to recognize that

$$E_{12}(f) = CO_{12}(f) - i Q_{12}(f)$$
 (12)

where CO is usually termed the cospectrum and Q is the quadrature spectrum, and

$$\phi_{12}$$
 (f) =  $\tan^{-1} \frac{Q_{12}$  (f)  $\cot^{-1} \frac{Q_{12}}{Q_{12}}$  (13)

Determining  $\phi$  from Eq. (13) also requires more computational time than the direct method of Eq. (8) if the waves are nearly periodic.

## Drag and Inertia Coefficients From C $_{\mu}$ and $\boldsymbol{\hat{\varphi}}$

We now assume that the horizontal velocity at the center position of the force transducer would be (in the absence of the cylinder)

$$u = u_{\mu} \cos\Theta \tag{14}$$

where  $\Theta=\omega t$  and  $\omega=2\pi/T$ , with T the wave period. Equation (1) can be non-dimensionalized by dividing both sides by  $D_{\rho}u_{\mu}^{2}/2$ , substituting Eq. (14), and defining the Keulegan-Carpenter number as  $K=u_{\mu}T/D$ , so that

$$\hat{F} = C_{d} \cos |\cos \theta| - \frac{\pi^{2}}{K} C_{m} \sin \theta . \tag{15}$$

It is sometimes useful to approximate Eq. (15) with a linear form by either expanding the  $\cos |\cos |\cos |$  in a Fourier series and retaining only the first term, or by utilizing the Lorentz linearization principle of equivalent work. In either case the result is

$$\hat{F} = .85 C_{d} \cos\Theta - \frac{2}{K} C_{m} \sin\Theta . \tag{16}$$

The approximate maximum value of  $\hat{F}$ , which is actually  $C_{\mu}$  from Eq. (2), is

$$C_{11} = \left[ \left( .85 \ C_{d} \right)^{2} + \left( \frac{\pi^{2}}{K} \ C_{m} \right)^{2} \right]^{1/2}$$
 (17)

and the phase between the wave crest (or  $\boldsymbol{u}_{\mu})$  and the maximum force is

$$\phi_{f} = \tan^{-1} \left( -\frac{\pi^{2} C_{m}}{.85 K C_{d}} \right)$$
 (18)

Equations (17) and (18) are almost virtually the same as Eqs. 3 and 4 (which were not derived) in Ref. (17), except for the .85 factor, which is necessary in the linearization procedure and was omitted in Ref. (17). Combining Eqs. (17) and (18) yields

$$C_{m} = \frac{.85 \text{ K C}_{d}}{\pi^{2}} \tan \left(-\phi_{f}\right) . \tag{19}$$

By substitution into Eq. (17), and with the identity,  $\cos\Theta = 1/(1 + \tan^2\Theta)^{1/2}$ , we obtain

$$C_{d} = 1.176 C_{\mu} \cos \phi_{f} \qquad (20)$$

Equation (19) can now be further simplified to

$$C_{m} = \frac{K C_{\mu} \sin(-\phi_{f})}{\pi^{2}} . \tag{21}$$

Equations (17), (20), and (21) are useful for making a rough estimate of the limits of drag or inertia dominance relative to Eq. (1). A more accurate and useful estimate of  $C_{\rm d}$  and  $C_{\rm m}$  will be derived later where a nonlinear form similar to Eq. (1) is retained.

Now consider the phase at which either the drag or inertia term dominates the maximum force coefficient,  $C_{\mu}$ , in Eq. (17). This is only a rough approximation because there is no universally accepted value for the concept 'domination'. For illustration, it is assumed that  $C_{\mu}$  is influenced only 4% by the inertia term. Then

$$C_{\mu} = .85 C_{d} \left[ 1 + \left( \frac{\pi^{2} C_{m}}{.85 K C_{d}} \right)^{2} \right]^{1/2}$$

$$= .85 C_{d} (1.04)$$
(22)

from which, in conjunction with Eq. (18),

$$\phi_{f} \simeq -16^{\circ}. \tag{23}$$

Likewise, if  $\textbf{C}_{\mu}$  is to be influenced only 4% by the drag term, then

$$\phi_f \simeq 74^{\circ}$$
 (24)

The Morison equation need not be linearized in order to obtain  $C_d$  and  $C_m$  as functions of  $C_\mu$  and  $\phi_f$ . Consider that the maximum force occurs near the leading surface of the wave crest, some time after the maximum acceleration and before the maximum velocity, as shown in Fig. 4. In that region

$$\hat{F} = C_d \cos^2 \Theta - \frac{\pi^2}{K} C_m \sin \Theta \tag{25}$$

and the maximum force will occur when

$$\frac{d\hat{F}}{d\Theta} = -2C_d \cos\Theta \sin\Theta - \frac{\pi^2}{K} C_m \cos\Theta = 0 . \qquad (26)$$

or,

$$\frac{d\hat{F}}{d\Theta} = -\cos\Theta \left(2 C_d \sin\Theta + \frac{\pi^2 C_m}{K}\right) = 0.$$
 (27)

Equation (27) must hold for all time, and at the force peak,  $\theta$  =  $\phi_f$ , so

$$\phi_{f} = \sin^{-1} \left( -\frac{\pi^{2} C_{m}}{2 K C_{d}} \right)$$
 (28)

By substitution into Eq. (25), and letting  $\cos^2\Theta = 1 - \sin^2\Theta$ ,

$$\hat{F}_{u} = C_{u} = C_{d} (1 - \sin^{2} \phi_{f}) - \frac{\pi^{2}}{K} C_{m} \sin \phi_{f},$$
 (29)

or,

$$C_{\mu} = C_{d} \left[ 1 - \left( -\frac{\pi^{2} C_{m}}{2 K C_{d}} \right)^{2} \right] - \frac{\pi^{2} C_{m}}{K} \left( -\frac{\pi^{2} C_{m}}{2 K C_{d}} \right) \frac{2 C_{d}}{2 C_{d}}$$
(30)

or,

$$C_{11} = C_{d} \left[1 - \gamma^{2} + 2 \gamma^{2}\right] \tag{31}$$

or,

$$C_{d} = C_{u} (1 + \gamma^{2})^{-1}$$
 (32)

where

$$\gamma = \sin \left(-\phi_{f}\right) = \frac{\pi^{2} C_{m}}{2 K C_{d}}.$$
 (33)

From Eq. (33)

$$C_{m} = \frac{2 K C_{d} \gamma}{2}$$
 (34)

and by substituting Eq. (32),

$$C_{m} = \frac{2 K C_{\mu}}{\pi^{2}} \frac{\gamma}{1 + \gamma^{2}} . \tag{35}$$

If  $\hat{\phi}$  and  $C_{\mu}$  are determined experimentally, then  $C_d$  and  $C_m$  can be estimated from Eqs. (32) and (35). The coefficient  $C_{\mu}$  is relatively independent of  $\Phi_f$ . However,  $\Phi_f$  can be influenced markedly by vortex shedding and the vagaries of the ambient flow. Laboratory data show that plots of  $C_{\mu}$  vs. K have relatively little scatter but the opposite is true for plots of  $\Phi_f$ .

Since both  $C_d$  and  $C_m$  are influenced by  $\phi_f$ , experimental values of them do have scatter.

#### Steady Tow Drag Coefficient

It is of interest to consider wave conditions with very large K because such values can exist for prototype (full scale) conditions in design sea state conditions. At some large K, nearly steady-state flow conditions should exist. In the OSU laboratory the maximum local K that can be obtained for the 8.625-inch diameter cylinder was about 26. However, steady-state towing was accomplished with a tow carriage, up to Reynolds number, R, of about  $1.7 \times 10^5$ . The drag coefficients,  $C_{\rm ds}$ , derived from such tests are defined as

$$C_{ds} = \frac{F_d}{\frac{1}{2} D \rho U^2}$$
 (36)

where  $\mathbf{F}_{\mathbf{d}}$  is the steady-state average drag force per unit of cylinder length and U is the steady flow velocity past the cylinder. The Reynolds number is

$$R = \frac{UD}{V} \tag{37}$$

where v is the kinematic viscosity of the fluid.

#### EXPERIMENTS

Most of the data presented herein are from references (3,11). However, limited results from the experiments reported in (18) will also be shown. A detailed review of the experiments can be found in those references and only a very brief review will be given here to acquaint the reader with the general aspects of the work.

#### Equipment

The Wave Research Laboratory (WRL) at OSU is a flume 12 feet wide, 15 feet deep (of which 3.5 feet is freeboard), and 340 feet long. The test length that is relatively free of the evanescent effects from boundary conditions is about 126 feet long. A longitudinal section of the facility is shown in Fig. 5. Horizontal cylinders were towed from a carriage as indicated in Fig. 6 for determining the steady-state drag coefficient,  $C_{\rm ds}$ , of the 8.625-inch diameter cylinders. Periodic waves were produced with periods ranging from 2.0 s to 6.0 s. The wave heights (trough-to-crest) were limited by incipient breaking up to a period of 2.6 s, where the wave height was about 5 feet. For periods greater than 2.6 s the maximum wave heights were limited by either the still water free board (3.5 feet) or the available energy from the wave generator (150 H.P.). The maximum height for the 6.0 s waves was 3 feet. Wave spectra were also produced, but the results therefrom will not be reported on herein. More details of the WRL and wave generation capabilities and characteristics can be found in (4,8,9).

The vertical 12.75-inch smooth aluminum cylinder (5) had a 12-inch long local force transducer that responded to the wave forces in a measurable way that was completely independent from the deflections, strains, and stresses

within the total cylinder structure. The vertical cylinder spanned smoothly from the wave flume floor to a beam 15 feet overhead, with no intermediate supports. The total forces and local pressures were also measured, but they will not be reported on here.

The vertical 8.625-inch diameter aluminum cylinder (11,12) also spanned from the wave flume floor to the overhead beam 15 feet above. However, it was necessary to provide intermediate supports at about 3.13 feet and 12.50 feet above the floor by means of small diameter, high strength guys that extended from the cylinder to the wave flume walls. The center of the local force transducer was at the same level as that for the 12.75-inch cylinder (3.7 feet below still water surface). However, the local forces were measured on a 2foot long section. The transducer was constructed in such a way (11) that deflections of the support column could introduce a 13% influence on the measurements of local force in the in-line forces. (The transverse forces were influenced only 4%.) However, this influence was accurately quantified during calibrations by loading the entire cylinder as well as the local force transducer. (Similar calibration procedures proved that the local force readings were independent of support column strains for the 12.75-inch cylinder.) Experiments with this equipment were also performed on a sand-roughened cylinder that had a relative roughness,  $\epsilon/D$ , of .023, where  $\epsilon$  is the average maximum height of the sand grains, which were first determined with a sieve analysis, and later corroborated with circumferential measurements. Some of these results will be presented here to illustrate analysis techniques.

The water surface profile was measured with a sonic profiler embedded in the beam that provided the top support for the cylinders. The water velocities were measured for each cylinder with Marsh McBirney current meters

placed midway between the vertical cylinder and the wave flume walls, and at the same elevation as the center of the local force transducers (3.7 feet below the still water surface).

### Measurements and Recording

Most measurement signals were recorded, filtered and unfiltered, wherein the filter was a Rockland 2-pole, low-pass filter with the cutoff frequency set at 8 Hz. The wave profiler was not filtered because of spurious results that would result from sharp 'spikes' or 'dropouts' that are inherent with sonic profilers and steep waves. Such records were filtered digitally. The current meter data were filtered in their own conditioning circuitry prior to the Rockland filter. Data processing included a calculation of the proper phase of each signal with the individual transfer functions so that the final smoothed signals were all properly phased with the water surface profile (3).

Signals were digitized at 256 increments per wave period. After complete processing, the data were reduced to 32 increments per wave, from which  $\mathrm{C_{d}}$ ,  $\mathrm{C_{m}}$ , and other quantities, such as plotted information, were calculated. This information was stored on magnetic tape. For the 12.75-inch cylinder, data from 10 waves were recorded for each run, from which 7 peak-to-peak waves were defined. For most of the 8.625-inch diameter cylinder runs, 4 waves were recorded, from which 3 peak-to-peak waves were defined. Extra runs were made for the 12.75-inch diameter cylinder. Most of the processing for those runs was done on 3 or 4 waves from the 10 waves recorded in order to save data reduction costs.

It will be of interest to consider the results of some experiments made with a 12.75-inch diameter smooth cylinder (18) wherein the cylinder was oscillated horizontally in otherwise still water at a distance of 6 diameters.

from the smooth bottom boundary and the still water surface. The apparatus was not constructed as well as for the vertical cylinders, so the results have considerable scatter. However, calibrations were carefully done and the central tendencies of the data trends are of considerable interest because Reynolds number of up to  $7 \times 10^5$  were achieved, as well as Keulegan-Carpenter numbers up to 63.

#### DATA ANALYSIS AND RESULTS

#### Water Kinematics and Dynamics

Although water velocities can be measured with current meters, it is not possible to measure the accelerations directly. They were, therefore, calculated from the velocity measurements. Basically, the time derivative of the velocity measurements must be made to obtain the accelerations. The noise in the velocity measurements is then amplified for the accelerations. Calculating the derivative in the time domain yielded unacceptable results, even after time-domain filtering and inverse phase shifting. However, a frequency-domain procedure was developed by performing a Fourier transform of the velocity measurement, applying a transfer function based on linear wave theory to obtain the acceleration spectrum, setting to zero the energies above a frequency of 1.0 Hz, and performing the inverse Fourier transform to obtain the acceleration in the time domain. The resulting acceleration is smoothed of high frequencies and is theoretically properly phased with the velocities. The procedure is reviewed in detail in (5). However, the author thinks there are inaccuracies in the magnitude and phase of the accelerations of an unknown amount due to innate inaccuracies in the velocity measurements. There is also scatter in the phase of the accelerations so determined for a reason that is as yet unknown.

In this section the kinematics and dynamics of the water particles will be reviewed. A brief review of the rms errors between the measured kinematics and the stream function theory appears in (10). Generally, the values ranged from .10 to .28. This is a rigorous criterion because the rms error, E, is based on the velocity vector. That is,

rms E = 
$$\left\{\frac{1}{N}\sum_{1}^{N}\left[\left(u_{m}-u_{\psi}\right)^{2}+\left(w_{m}-w_{\psi}\right)^{2}\right]_{i}\right\}^{1/2}/u_{\mu m}$$
 (38)

where the subscript, m, is the measured value, and  $\psi$  is the value from stream function theory for the horizontal velocity, u, and the vertical velocity, w. Three somewhat typical results from kinematic measurements appear in Figs. 7, 8, and 9.

The phase shift of the acceleration,  $\phi_a$  (see Fig. 4) can be predicted from stream function theory. Values of  $\phi_a$  within the range of these experiments are plotted as the solid lines in Fig. 10, as a function of the wave height, H, and period, T. In addition, values were computed from the velocity measurements for the runs for the 12.75-inch cylinder. Each run had one value for each of the 7 waves measured. The average values of these for each run are also plotted in Fig. 10. The results show only rough agreement. It is concluded that errors in velocity measurements, even though they may be small, are amplifed considerably when accelerations are calculated therefrom. This is particularly true for the phase of the positive peak of the accelerations. Therefore, for the remainder of the analyses, it was decided to rely on the phase of the accelerations as determined from stream function theory.

In a closed system wave flume there is mass transport from the wave generator toward the beach in the general region above the wave troughs. This must be balanced by a return flow from the beach toward the wave generator, possibly at some depths below the troughs. The return flow was calculated by Kim (6) using Stokes fifth order wave theory and by assuming the return flow is uniform from the bottom of the flume up to the still water level. The return flow was also calculated from the kinematics measurements and the averages from a limited set of data are shown in Fig. 11. [They are also shown in a different way in (10).]

A broad agreement can be detected between measurements and theory. There is still considerable scatter, which is due to measurement errors and the fact that  $\bar{u}$  is probably a function of time, whereas the theory is based on steady-state conditions. For the analyses herein  $\bar{u}$  was determined from Fig. 11 and vectorially added to  $\bar{u}$  from the stream function theory for analytical purposes here needed.

### Phase Shift, \$\phi\$, Normalized With 90°

It is desired to compare the different methods for determining  $\hat{\phi}$ . This was done for a cylinder uniformly coated with sand, such that the relative roughness,  $\epsilon/D$ , was .023. The cylinder is designated as the SRC.02 and the phase was determined by the peak-to-peak method, the crossings method (average of the zero upcrossings and zero downcrossings), and the cross-correlation method. In each case the normalizing value used was  $90^{\circ}$ . This was done in an early phase of this work and was reported in (13). It is repeated here for completeness in order to compare the results of the different methods used on one cylinder. The SRC.02 (Sand Roughened Cylinder, k/D = .023) was also selected for this comparison because the results should be more influenced by the velocity (drag effects) than for the smooth cylinders.

These results for the SRC.02 are shown in Fig. 12. They show fairly tight plots for the zero crossings method and the cross-correlation method. The peak-to-peak method has more scatter, particularly at the higher K values. Figure 12 shows clearly that the  $\hat{\phi}$  values are lowest for the peak-to-peak method, highest for the zero crossings method, and in-between for the cross-correlation method. These relationships are to be expected since velocities are low at the crossings, highest in the crest region, and averaged out for the cross-correlation method. Since the crest region of the wave is of

most interest and since the maximum force coefficient is determined from the maximum value of the force and the maximum velocity, the peak-to-peak method will be emphasized in the remaining part of this paper.

The 12.75-inch cylinder will henceforth be designated as the VSMC12 (Vertical Smooth Cylinder) and the 8.625-inch cylinder as the VSMC8. Selected runs for the VSMC12 were analyzed for  $\hat{\phi}$  by using the cross-correlation and cross-spectrum analyses. The results are shown in Fig. 13. In fact, for a given K, the two methods were practically equal, though not identical. The data points were purposefully displaced in order to show for which points both analyses were made. Figure 14 shows the results for the zero crossings method. The phase,  $\phi_{\rm f}$ , is evidently smoothly changing from 1.0 to smaller values at a K of 15.

The results from the peak-to-peak method of finding  $\hat{\phi}$  are shown in Fig. 15. The dashed line was constructed first for the VSMC12 alone, then for the VSMC8. The two curves were close, so an average was struck, which is represented by the dashed line up to about K = 20. The remainder of the line was drawn, taking into account the scatter from the horizontal 12.75-inch diameter cylinder (HSMC12). Obviously, more data are needed in the range 20 < K < 200.

## Maximum Force Coefficient

The maximum force coefficient,  $C_{\mu}$ , for the VSMC12 is shown in Fig. 16 wherein the value of  $u_{\mu}$  is from the measured kinematics. Figure 17 shows the same information using  $u_{\mu}$  as determined from the stream function theory. There is a little less scatter, particularly for K < 10, for the data based on stream function kinematics than for those based on the measured kinematics. Hence, it was decided to show most of the remaining data based on stream function kinematics wherever possible. Actually, even the seemingly small

scatter in Fig. 17 can be reduced further, as shown, approximately according to  $\beta$ . The A line roughly represents the data for the larger  $\beta$  values and the B line roughly represents the data for the smaller  $\beta$  values. It was seen in (13) that  $C_{\mu}$  vs. K data can be organized quite well for very rough cylinders, and it was assumed at that time that they collapsed to a single line for smooth cylinders. However, the carefully plotted information in Fig. 17 shows that smooth cylinder data may be further organized according to  $\beta$  even for the higher values of  $\beta$ .

It is also of interest to note that for small K Eq. (25) can be expressed accurately with only the second term. Then, taking

$$\hat{\mathbf{F}}_{\mu} = \mathbf{C}_{\mu} = \frac{\pi^2 \, \mathbf{C}_{\mathbf{m}}}{\mathbf{K}} \tag{39}$$

it can be seen that the slope of the plot in Fig. 17 should be -1, which is nearly the case.

Figure 18 is the similar plot for the VSMC8. The  $\beta$  breakdown is indicated and it appears to be close to that for Fig. 17. That is, the A and B lines fall nearly at the same positions.

However,  $C_{\mu}$  for higher values of K are needed to show how  $C_{\mu}$  varies for all values, knowing that it should approach  $C_{ds}$  as K gets large, according to Eq. (31). Some approximate data were obtained from the experiment records that were accomplished for (18). Plots for the VSMC12, VSMC8, and the HSMC12 are summarized in Fig. 19. From these data it seems to be reasonable to use the curves as drawn to approximate the relation of  $C_{\mu}$  to K for all values of K. Of course, these are tentative curves that need to be verified with additional data at high K values from any valid available source. The value of  $C_{ds}$  in the figures is the average of several tow tests made with the smooth

aluminum 8.625-inch diameter cylinders up to R values of  $7 \times 10^5$ . The values ranged between .4 and .6.

It is of interest to note that it <u>may</u> be possible, as indicated in Fig. 19, that  $C_{\mu}$  can be determined at laboratory scales <u>for all values of K</u> if the high values are determined from  $C_{ds}$  and the low values are up to high enough K so that  $C_{\mu} \simeq C_{ds}$ . This also implies for all values of R! It will be seen shortly that the same is not true for  $\hat{\phi}$  or  $\tilde{\phi}$ .

## Phase Shift, $\tilde{\phi}$ , Normalized With $\phi_a$

Attention is now directed toward  $\tilde{\phi}$  to see for what values of K the force record is nearly in phase with the velocity record (drag-dependent). Figure 10 shows that as K increases (i.e., as H and/or T increase),  $\phi_a$  gets smaller. It turns out that  $\tilde{\phi}$  from Eq. (4) remains quite high because although the maximum force becomes more closely in phase with u, the phase of  $\tilde{u}$  also moves toward that of u, so that  $\tilde{\phi}$  reduces only slowly, as shown in Fig. 20. Since  $\phi_a$  is dependent on measured values of H and T, there is considerably more scatter in  $\tilde{\phi}$ . Thus, the forces measured were heavily dominated by the acceleration effects up to K values even as high as 23.

## Drag and Inertia Coefficients

The normalized phase,  $\hat{\phi}$ , is plotted for the VSMC12, VSMC8, and the HSMC12 in Fig. 15. This figure and Fig. 19, along with Eqs. (32) and (35), were used to obtain values of  $C_d$  and  $C_m$  that would yield best approximations of the magnitude of the maximum force.

The values of  $C_d$  and  $C_m$  are shown in Fig. 21, where the smooth curves are from Eqs. (32), (33), and (35), using the smooth curve values of  $C_\mu$  and  $\phi f$  determined from Figs. 15 and 19. The plotted points in Fig. 21 are the values

of  $C_{\rm d}$  and  $C_{\rm m}$  determined from the respective cylinders, as calculated with least squares methods (5) and averaged over a minimum of three waves in any run, and up to seven in some.

It is possible that the scatter in data values of  $C_d$  and  $C_m$  in Fig. 21 can be further organized according to broad ranges of R and  $\beta$ . Actually, data indicate  $C_\mu$  can be organized according to  $\beta$ , when plotted as a function of R. Equations (32) and (35) can be transformed to functions of R and  $\beta$  through  $K = R/\beta$ . So, this further refinement, or organization of the scatter according to  $\beta$ , is left for a future effort.

#### CONCLUSIONS

- The relative phase shifts between the maximum velocity, the maximum measured force, and the maximum acceleration show immediately whether a wave and cylinder diameter arrangement will produce conditions that are acceleration- (inertia) or velocity- (drag) dependent. Up to a K of at least 25, the local wave force on a smooth vertical cylinder is heavily dependent on the fluid acceleration.
- A plot of the maximum force coefficient,  $C_{\mu}$ , vs. K, the Keulegan-Carpenter number, can be generated for all K (which implies for all R) with waves at least as large as those produced in the Oregon State University Wave Research Laboratory, in conjunction with steady tow tests at Reynolds number at least well beyond the critical value (up to about  $7 \times 10^5$ ).
- Laboratory results are mostly limited from determining accurate values of the phase of the force measurement,  $\phi_f$ , at higher K values. Data plots of  $\hat{\phi}$  vs. K, up to a K of from 25 to 60, indicate that the force is still strongly influenced by the acceleration (inertia) effects. Only for roughened cylinders can laboratory results at OSU show dominant drag conditions at higher K values.

#### SUGGESTIONS FOR FUTURE STUDIES

- The <u>total</u> in-line force acting on the VSMC12 cylinder can be determined from existing measurement data. The phase of the total force should not necessarily be the same as that of the local measured force because the drag term in the Morison equation has its greatest influence in the region between the wave trough and crest. The phases of the top and bottom reactions (both were measured) can be determined analytically using the local force measurement as a benchmark. Thus the measured and analytical phases of the total force with respect to the local force can be compared. It is possible that the total force will be more influenced by the drag effects because the Keulegan-Carpenter number is higher in the trough-to-crest region.
- with respect to a maximum force coefficient concept in conjunction with the phase of the transverse force. This can probably be accomplished with spectrum analysis techniques. These measurements and analyses could be compared to the 8 local pressure measurements for verification.
  - Maximum force coefficient and phase angle can be utilized for organizing the random wave forces. The Keulegan-Carpenter number can be associated with the frequency and spectrum amplitudes and the maximum force coefficient can be related to the velocity and force spectra. The  $C_\mu$  and  $\hat{\phi}$  can probably be well represented as functions of wave frequency. The influence of nonlinearities may introduce problems, but a linear assumption could be made as a first approximation. Values of  $C_d$  and  $C_m$  obtained in this manner can be compared to values obtained by a conventional wave-by-wave analysis.

#### **ACKNOWLEDGEMENTS**

The author wishes to express his gratitude to the Minerals Management Service and to the Naval Civil Engineering Laboratory for support of this study through contract No. N62474-82-C08295. Mr. Charles Smith and Mr. Jerry Dummer provided personal support. Computational and plotting assistance were well provided by graduate students in the Ocean Engineering Program at OSU, particularly Mr. Chung-Chu Teng, Mr. Ming-Kuang Hsu, and Mr. Jerry Ramsden.
